Abstract

Potato (*Solanum tuberosum* L.) is the fourth most important agricultural crop after wheat, rice, and maize around the world, so increasing its quality (with a low amount of contaminants) is very important and notable. If for any reason, Cadmium (Cd) concentration increases in the soil, its uptake by the potato will be increased as a result. One of the main sources of Cd in the soil is the application of imbalanced fertilization especially consuming imported phosphate fertilizers. In order to investigate the effect of different sources of P-fertilizers on the Cd accumulation in potato tubers, an experiment was carried out on a farm in Dehgolan, Iran. This experiment was conducted based on a Randomized Complete Block Design (RCBD) with three replications. Before starting the experiment, soil and P-fertilizer samples were taken and analyzed in the laboratory. The concentration of soil available P, Zn, and Cd were 8.0, 0.75, and 0.15 mg kg⁻¹ respectively and the concentration of Cd in different P-fertilizers were 5, 15, and 25 mg kg⁻¹ respectively. Experimental treatments were: T₁ (control) = Without P; T₂ = T₁+RP (Rock Phosphate); T₃ = T₁+SSP (Simple superphosphate) and T₄ = T₁+TSP (Triple superphosphate). The results revealed that Cd concentration in T₁ was 0.10, in T₂ was 0.13, in T₃ was 0.25 and in T₄ was 0.29 mg kg⁻¹. Thus, TSP caused maximum, and RP caused the least Cd accumulation in potato tubers (p < 0.01). According to the obtained results, it can be concluded that application of P-fertilizers should be based on the soil test results and using rock phosphate and simple superphosphate should become a priority, we have to select P-fertilizers which has the lowest Cd concentration, and to take care of controlling the quality of imported P-fertilizers especially their Cd content.

Keywords: Potato (*Solanum tuberosum* L.), P-Fertilizers, Phosphorus (P) and Cadmium (Cd)

Introduction

Potato (*Solanum tuberosum* L.) is the fourth largest food crop after wheat, rice and corn. The presence of a variety of vitamins, especially vitamin C, along with other essential minerals and proteins in potatoes, has made its consumption as a valuable food in the world, so that 2.5% of the daily energy of the world population is provided by potatoes. The per capita consumption of potatoes in the world is 100 and in Iran 45kg per year and its average yield in the world is 40 and in Iran is 30 tons per hectare [1].

Cadmium is a heavy metal that its presence in the ecosystem is very dangerous for living organisms [2]. Absorption of this element by the plant leads to damage such as destruction of the nucleus, inhibition of the activity of some enzymes, necrosis and yellowing of leaves, reduced root and stem growth, reduced water absorption, reduced chlorophyll and carotenoids and inhibition of opening the stomata [3]. Cadmium is also a threat to human health, it is easily absorbed by the human digestive tract. 50% of the cadmium absorbed in the body, accumulates in the liver and kidneys and its half-life in the human body is between 10 and 30 years [4]. Toxic effects of cadmium on human include destruction of kidneys and liver tissue,

carcinogenesis and emphysema [5].

Samavat et al. [6] reported that the consumption of phosphate fertilizers by farmers in the paddy fields of the north of the Iran increased the amount of soil cadmium by 15.5% in two years, which in turn caused contamination of rice. Preliminary studies on the concentration of cadmium in pistachios and dates have shown its amount to be equal to 0.48 and 0.12 mg kg⁻¹ dry matter, respectively. Bybordi and Malakouti [7] reported that the highest cadmium concentration was measured if 150 kg ha⁻¹ P was applied without zinc (Zn). The results of these researchers showed that adding zinc to the soil reduced the concentration of cadmium in the tubers. The highest amount of phosphorus in the tubers was measured at 150 kg ha⁻¹ without the use of zinc. Asbaghian et al. [8] whose worked on a research on the effect of Zinc fertilizers on the cadmium concentration in potato tubers, concluded that there was a significant difference (p < 0.01) between Cd concentration in control treatment and treatments in which Zn-fertilizers have been used. The maximum Cd concentration has observed in control treatment with 0.13 mg kg⁻¹ fresh weight and the minimum has obtained from SSOP+Zn chelate treatment by 0.01 mg kg⁻¹ fresh weight. The maximum acceptable concentration of Cd in peeled potatoes according to the standard of

the National Standard Organization of Iran and other international organizations is 0.10 mg kg^{-1} fresh weight of the plant [8]. Rahmani [9] in the study of the long-term effect of phosphate fertilizers on soil and plant cadmium concentration and environmental hazards in some areas of Isfahan province contaminated with cadmium metal showed that the concentration of soil cadmium in potato cultivated lands was in the range of 0 to 4 mg kg^{-1} and with an average of 1.98 mg kg^{-1} of dry soil. In this study, the concentration of cadmium in potato tubers and during five consecutive years of cultivation was reported to be 0 to 12.3 mg kg^{-1} dry matter. Due to the acceptable concentration of cadmium in potato crop (0.20 mg kg^{-1} fresh weight), the amount of cadmium accumulated in the potato tuber of the Daran region was more than threshold level and there is possibility of contamination and complication of cadmium in the plant, livestock and human body. McLaughlin et al. [10] reported that with the application of 200 kg ha^{-1} of phosphorus fertilizer (30 mg kg^{-1}) per year in the potato field, 6 g ha^{-1} of cadmium enters the soil. The amount of cadmium in potato tubers ranged from 0.50 to 30 mg kg^{-1} . The amount of cadmium entering the soil by phosphate fertilizers was from 8.2 to 40 and the amount of cadmium leaving by tubers was from 0.80 to 6.9 g ha^{-1} . The reduction of cadmium concentration in tubers by 25-50% due to the zinc fertilizer's application, also will be affected by the type of fertilizer, factors such as soil pH, soil texture, soil organic matter, type of soil clay and also the plant variety. Therefore, the aim of this study was to investigate the effect of different sources of phosphate fertilizers on the accumulation of cadmium in potato tubers.

Materials and Methods

This experiment was performed in potato fields of Dehgolan city located in Kurdistan province, Iran. After selecting the desired land for the experiment, sampling was done randomly and mixed samples were prepared. The soil samples were air-dried and passed through a 2mm sieve to analyze some physical and chemical properties. This experiment was performed in a randomized complete block design with four treatments and three replications (blocks). The first treatment included the control treatment in which the optimal application of fertilizers was observed based on the results of soil analysis except for phosphate fertilizer; The second treatment included control treatment in addition to Rock Phosphate (RP); The third treatment included control treatment in addition to supplying phosphorus from Simple Superphosphate Fertilizer (SSP) and the fourth treatment included control treatment in addition to supplying phosphorus from Triple Superphosphate Fertilizer (TSP). Potato tubers were harvested after the completion of the growing season (mid-November). After harvesting, the samples were thoroughly washed with distilled water. Each was then weighed separately and placed in separate bags. The samples were dried at 70°C in a ventilated oven and weighed again. The dried samples were thoroughly pulverized with an electric mill for chemical analysis and stored in special containers. Simultaneously, with the harvest of plant samples, soil samples were also taken from different plots, and after

air drying, the samples were completely crushed and passed through a 2mm sieve. They were then taken to a laboratory for chemical tests. Physical and chemical properties of soil samples including soil texture were measured by hydrometric method, organic carbon by Walkley and Black method, and calcium carbonate equivalent by reverse titration with hydrochloric acid [11]. Nitrogen concentration was measured by the Kjeldahl method, phosphorus by Olsen method by spectrophotometer, and potassium by flame photometer. In this study, a sample of water-to-soil suspension was prepared and the Electrical Conductivity (EC) and soil reaction (pH) of the extracts were determined using conductometers and pH meters, respectively [12]. In this study, DTPA extract (diethylenetriamine pentaacetic acid) in 0.01 M calcium chloride base solution was used to measure cadmium and zinc absorbable elements in the soil. 10 g of soil was weighed and poured into 125 ml Erlenmeyer. Then 20 ml of DTPA solution was added. The lid was then closed and shaken for two hours with a shaker (GFL rotary shaker 145 rpm) and smoothed with Whatman 42 filter paper. Then the concentrations of zinc and cadmium in the extract were read by ICP-OES. Also in this study, the wet digestion method (digestion with a mixture of nitric acid, perchloric acid and sulfuric acid) was used to measure cadmium and zinc in the plant [13]. To measure the percentage of dry matter, several large, medium and small tubers were washed and dried with ordinary water and distilled water, respectively. After weighing, the tubers were cut into thin slices and placed in an oven at 75°C for 48 hours to dry completely. Then the dry weight of the samples was measured and the percentage of dry matter of tubers was calculated. SPSS 18 software was used to compare treatments and analyze variance. Relevant graphs and tables were drawn with Excel software and Duncan's multiple range test at the probability level of 0.01 and 0.05 was used to compare the means.

Results and Discussion

The results of some physical and chemical properties of soil before planting are presented in Table 1.

Table 2 presents the results of analysis of variance of the effect of different treatments of phosphate fertilizer on the concentration of phosphorus in the soil. The results of this table show that different sources of phosphate fertilizers have caused significant differences in the concentration of phosphorus in the soil and at a statistical level of 5% ($\alpha = 5\%$). Figure 1 shows the concentration of soil phosphorus in different treatments of phosphate fertilizers. According to this figure, different sources of phosphate fertilizers have caused significant differences in the concentration of phosphorus in the soil compared to the control treatment. So that the lowest concentration of phosphorus in the soil is related to the control treatment with a concentration of 5 mg kg^{-1} and the highest is related to the triple superphosphate treatment with a concentration of 16 mg kg^{-1} .

Table 3 shows the results of analysis of variance of the effect of different treatments of phosphate fertilizer on the concentration of cadmium in the soil. According to the table, it can be seen that

different sources of phosphate fertilizers have caused significant differences in the concentration of cadmium in the soil and at a statistical level of 1% ($\alpha = 1\%$).

Figure 2 also shows the concentration of soil cadmium in different treatments of phosphate fertilizers. According to this figure, different sources of phosphate fertilizers have caused significant differences in the concentration of cadmium in the soil compared to the control treatment. The results show that the lowest concentration of cadmium in the soil is related to the control treatment with a concentration of 0.15 mg kg⁻¹ and the highest is related to the triple superphosphate treatment with a concentration of 0.35 mg kg⁻¹.

of different treatments of phosphate fertilizers on the yield of potato tubers. As can be seen in this table, different sources of phosphate fertilizers caused a statistically significant difference at the level of 5% ($\alpha = 5\%$) in the yield of potato tubers compared to the control treatment.

Figure 3 also shows the hectare yield of potato tubers in different treatments of phosphate fertilizers. As can be seen in this figure, different sources of phosphate fertilizers have caused significant differences in the yield of potato tubers compared to the control treatment. According to this figure, the lowest yield of potato tubers is related to control treatment with 33 tons per hectare and the highest amount is related to phosphate soil treatment with 37 tons per hectare. The results also show that there is no significant difference between the yields of potato tubers resulting from different treatments of

Figure 3: The potato tubers yield at phosphate fertilizers different treatments.

phosphate fertilizers.

Table 5 presents the results of analysis of variance of the effect of different treatments of phosphate fertilizers on the phosphorus concentration of potato tubers. The results of this table show that different sources of phosphate fertilizers cause statistically significant differences at level of 5% ($\alpha = 5\%$) in the phosphorus concentration of potato tubers.

Figure 4 shows the phosphorus concentration of potato tubers in different treatments of phosphate fertilizers. Due to this form, different sources of phosphate fertilizers have caused significant differences in the phosphorus concentration of potato tubers compared to the control treatment. The results show that the lowest concentration of phosphorus in potato tubers is related to the control treatment with a concentration of 0.10% and the highest is related to the triple superphosphate treatment with a concentration of 0.18%.

Table 6 shows the results of analysis of variance of the effect of different treatments of phosphate fertilizers on the cadmium concentration of potato tubers. According to this table, different sources of phosphate fertilizers have caused a statistically significant difference at the level of 5% in the cadmium concentration of potato tubers.

Figure 5 also shows the cadmium concentration of potato tubers in different treatments of phosphate fertilizers.

As this figure shows, different sources of phosphate fertilizers have caused significant differences in the cadmium concentration of potato tubers compared to the control treatment (0.10 mg kg⁻¹). Among the various sources of phosphate fertilizers, the lowest concentration of cadmium in potato tubers was related to rock phosphate treatment with a concentration of 0.13 and the highest was related to triple superphosphate treatment with a concentration of 0.29 mg kg⁻¹. Also, the concentration of cadmium in potato tubers in simple superphosphate treatment was 0.25 mg kg⁻¹.

The results showed that there was no significant difference between the amounts of yield in different treatments of phosphate fertilizer. Decreased yield in simple and triple superphosphate treatments may be due to the negative interaction between phosphorus and zinc or between cadmium and zinc, which ultimately reduces the uptake of zinc and thus the yield of potato tubers [8]. Dadkhah [14] reported that the highest yield of potato tubers was obtained with the application of 80 kg ha⁻¹ of zinc sulfate and the lowest yield was obtained with the non-application of zinc sulfate. The results showed that with increasing the amount of cadmium in the soil, the concentration of this element in potato tubers increased significantly. According to Figure 5, the amount of cadmium in potato tubers in the control treatment and rock phosphate treatment is less than the allowable limit and in simple superphosphate and triple superphosphate treatments is higher than the acceptable limit (the acceptable limit of cadmium in the tuber Potatoes are equal to 0.20 mg kg⁻¹ [15]. Due to the low mobility of cadmium in the plant, most of this element accumulates in the roots of the plant (especially the tubers) and small amounts of it are transferred to aerial organs such as leaves [8]. According to the results, with increasing the concentration of cadmium in the tubers, the concentration of zinc decreased, which is due to the negative interaction with cadmium. According to Malakouti [4], zinc and cadmium due to ionic similarity, have a negative interaction in the soil during plant uptake, so that increasing the concentration of zinc in the soil reduces the uptake of cadmium through the plant due to competition between zinc and cadmium. Therefore, in this study, in the almost constant concentration of zinc in the soil, in the triple superphosphate treatment, the highest and in the control treatment, the lowest amount of cadmium concentration was observed in the tubers. Also, the highest concentration of zinc in the tubers was related to the control treatment and the lowest concentration was in the triple superphosphate treatment. Koleli et al. [16] reported that zinc application usually reduces the uptake and accumulation of cadmium in plants due to competition with cadmium. Nan et al. [17] also reported that zinc consumption decreased cadmium concentrations in wheat and corn and the amount of this reduction was higher in wheat. The researchers also showed that cadmium accumulation is higher in zinc-deficient soils. According to the results, with increasing the concentration of phosphorus in the

tubers, the concentration of cadmium also increased, which may be due to the negative interaction of phosphorus with zinc. Due to this negative interaction, the uptake of zinc decreased and since cadmium and zinc also compete for uptake, the uptake of cadmium increased. McLaughlin et al. [10] reported that by applying 80 kg ha⁻¹ of phosphorus (assuming a cadmium concentration of 250 mg kg⁻¹), 20 g ha⁻¹ of cadmium enters the soil on a potato field.

Conclusion

In general, according to the results, it is inferred that different sources of phosphate fertilizers cause the accumulation of different amounts of cadmium in potato tubers. In addition to the type of phosphate source, the interaction of phosphorus and zinc is also effective in the accumulation of cadmium in potato tubers. Due to the fact that the type of phosphate source did not have much effect on the yield of potato tubers, so in terms of quality (increasing dry matter percentage and decreasing cadmium concentration), rock phosphate treatment resulted in the production of higher quality tubers. The results showed that the consumption of phosphorus from triple superphosphate sources and even simple superphosphate with a content of more than 10 mg kg⁻¹ of cadmium, led to the unauthorized accumulation of cadmium in potato tubers. Therefore, with the optimal use of phosphate fertilizers and fertilizers containing zinc (especially zinc sulfate), the concentration of cadmium (as a contaminant) can be reduced and the concentration of zinc (as an essential element) can be increased. Therefore, it is recommended that the use of chemical fertilizers, especially phosphate fertilizers, be done through the results of soil analysis. In addition, the amount of phosphate fertilizers used, taking into account the total phosphorus and its critical limit in arable soils, is saved and the entry of phosphate fertilizers or rock phosphate containing more than 15 mg kg⁻¹ of cadmium is prevented. Also, due to zinc deficiency in agricultural lands and crops in the Iran, it is suggested that more research be done on the effect of phosphate fertilizers in aggravating the deficiency of this element.
